This paper describes a recursive method for the LU factorization of sparse matrices. The recursive formulation of common linear algebra codes has been proven very successful in dense matrix computations. An extension of the recursive technique for sparse matrices is presented. Performance results given here show that the recursive approach may perform comparable to leading software packages for sparse matrix factorization in terms of execution time, memory usage, and error estimates of the solution.

1. Introduction

Typically, a system of linear equations has the form:

$$Ax = b, \quad (1)$$

where A is n by n real matrix ($A \in \mathbf{R}^{n \times n}$), and x and b are n -dimensional real vectors ($b, x \in \mathbf{R}^n$). The values of A and b are known and the task is to find x satisfying Eq. (1). In this paper, it is assumed that the matrix A is large (of order commonly exceeding ten thousand) and sparse (there are enough zero entries in A that it is beneficial to use special computational methods to factor the matrix rather than to use a dense code). There are two common approaches that are used to deal with such a case, namely, iterative [33] and direct methods [17].

Iterative methods, in particular Krylov subspace techniques such as the Conjugate Gradient algorithm, are the methods of choice for the discretizations of elliptic or parabolic partial differential equations where

the resulting matrix is often guaranteed to be positive definite or close to it. However, when the linear system matrix is strongly unsymmetric or indefinite, as is the case with matrices originating from systems of ordinary differential equations or the indefinite matrices arising from shift-invert techniques in eigenvalue methods, one has to revert to direct methods which are the focus of this paper.

In direct methods, Gaussian elimination with partial pivoting is performed to find a solution of Eq. (1). Most commonly, the factored form of A is given by means of matrices L , U , P and Q such that:

$$LU = PAQ, \quad (2)$$

where:

- L is a lower triangular matrix with unitary diagonal,
- U is an upper triangular matrix with arbitrary diagonal,
- P and Q are row and column permutation matrices, respectively (each row and column of these matrices contains single a non-zero entry which is 1, and the following holds: $PP^T = QQ^T = I$, with I being the identity matrix).

A simple transformation of Eq. (1) yields:

$$(PAQ)Q^{-1}x = Pb, \quad (3)$$

which in turn, after applying Eq. (2), gives:

$$LU(Q^{-1}x) = Pb, \quad (4)$$

Solution to Eq. (1) may now be obtained in two steps:

$$Ly = Pb \quad (5)$$

$$U(Q^{-1}x) = y \quad (6)$$

and these steps are performed through forward/backward substitution since the matrices involved are triangular. The most computationally intensive part of solving Eq. (1) is the LU factorization defined by Eq. (2). This operation has computational complexity of order $O(n^3)$ when A is a dense matrix, as compared to $O(n^2)$ for the solution phase. Therefore, optimiza-

tion of the factorization is the main determinant of the overall performance.

When both of the matrices P and Q of Eq. (2) are non-trivial, i.e. neither of them is an identity matrix, then the factorization is said to be using complete pivoting. In practice, however, Q is an identity matrix and this strategy is called partial pivoting which tends to be sufficient to retain numerical stability of the factorization, unless the matrix A is singular or nearly so. Moderate values of the condition number $\kappa = \|A^{-1}\| \cdot \|A\|$ guarantee a success for a direct method as opposed to matrix structure and spectrum considerations required for iterative methods.

When the matrix A is sparse, i.e. enough of its entries are zeros, it is important for the factorization process to operate solely on the non-zero entries of the matrix. However, new nonzero entries are introduced in the L and U factors which are not present in the original matrix A of Eq. (2). The new entries are referred to as fill-in and cause the number of non-zero entries in the factors (we use the notation $\eta(A)$ for the number of nonzeros in a matrix) to be (almost always) greater than that of the original matrix A : $\eta(L + U) \geq \eta(A)$. The amount of fill-in can be controlled with the matrix ordering performed prior to the factorization and consequently, for the sparse case, both of the matrices P and Q of Eq. (2) are non-trivial. Matrix Q induces the column reordering that minimizes fill-in and P permutes rows so that pivots selected during the Gaussian elimination guarantee numerical stability.

Recursion started playing an important role in applied numerical linear algebra with the introduction of Strassen's algorithm [6,31,36] which reduced the complexity of the matrix-matrix multiply operation from $O(n^3)$ to $O(n^{\log_2 7})$. Later on it was recognized that factorization codes may also be formulated recursively [3,4,21,25,27] and codes formulated this way perform better [38] than leading linear algebra packages [2] which apply only a blocking technique to increase performance. Unfortunately, the recursive approach cannot be applied directly for sparse matrices because the sparsity pattern of a matrix has to be taken into account in order to reduce both the storage requirements and the floating point operation count, which are the determining factors of the performance of a sparse code.

2. Dense recursive LU factorization

Figure 1 shows the classical LU factorization code which uses Gaussian elimination. Rearrangement of

```
function xGETRF(matrix ( $\mathbf{R}^{n \times n} \ni$ )  $A \equiv [a_{ij}]$ ;  $i, j = 1, \dots, n$ )
begin
  for  $i = 2, \dots, n$  do
    begin
       $a_{ij} := \frac{1}{a_{jj}}(a_{ij} - \sum_{k=1}^{j-1} a_{ik}a_{kj})$ ;  $j = 1, \dots, i-1$ 
       $a_{ij} := (a_{ij} - \sum_{k=1}^{i-1} a_{ik}a_{kj})$ ;  $j = i, \dots, n$ 
    end
  end
```

Fig. 1. Iterative LU factorization function of a dense matrix A . It is equivalent to LAPACK's `xGETRF()` function and is performed using Gaussian elimination (without a pivoting clause).

the loops and introduction of blocking techniques can significantly increase the performance of this code [2, 9]. However, the recursive formulation of the Gaussian elimination shown in Fig. 2 exhibits superior performance [25]. It does not contain any looping statements and most of the floating point operations are performed by the Level 3 BLAS [14] routines: `xTRSM()` and `xGEMM()`. These routines achieve near-peak MFLOP/s rates on modern computers with a deep memory hierarchy. They are incorporated in many vendor-optimized libraries, and they are used in the Atlas project [16] which automatically generates implementations tuned to specific platforms.

Yet another implementation of the recursive algorithm is shown in Fig. 3, this time without pivoting code. Experiments show that this code performs equally well as the code from Fig. 2. The experiments also provide indications that further performance improvements are possible, if the matrix is stored recursively [26]. Such a storage scheme is illustrated in Fig. 4. This scheme causes the dense submatrices to be aligned recursively in memory. The recursive algorithm from Fig. 3 then traverses the recursive matrix structure all the way down to the level of a single dense submatrix. At this point an appropriate computational routine is called (either BLAS or `xGETRF()`). Depending on the size of the submatrices (referred to as a block size [2]), it is possible to achieve higher execution rates than for the case when the matrix is stored in the column-major or row-major order. This observation made us adopt the code from Fig. 3 as the base for the sparse recursive algorithm presented below.

3. Sparse matrix factorization

Matrices originating from the Finite Element Method [35], or most other discretizations of Partial Differential Equations, have most of their entries equal to

```

function xGETRF(matrix  $A \in \mathbf{R}^{m \times n}$ )
begin
  if ( $A \in \mathbf{R}^{n \times 1}$ )
    begin
       $|a_{k1}| := \max_{1 \leq i \leq n} |a_{i1}|$ 
       $a_{11} := a_{k1}$ 
       $A := \frac{1}{a_{11}} \cdot A$ 
    end
  else begin

     $m_1 := \lfloor m/2 \rfloor$ ;  $n_1 := \lfloor n/2 \rfloor$ ;
     $m_2 := m - \lfloor m/2 \rfloor$ ;  $n_2 := n - \lfloor n/2 \rfloor$ ;

     $A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \in \mathbf{R}^{m \times n}$ 
     $A_{11} \in \mathbf{R}^{m_1 \times n_1}$ ,  $A_{21} \in \mathbf{R}^{m_2 \times n_1}$ ,  $A_{12} \in \mathbf{R}^{m_1 \times n_2}$ ,  $A_{22} \in \mathbf{R}^{m_2 \times n_2}$ 

    xGETRF( $\begin{bmatrix} A_{11} \\ A_{21} \end{bmatrix}$ );

    xLASWP( $\begin{bmatrix} A_{12} \\ A_{22} \end{bmatrix}$ );

    Find  $X_{12}$  such that:  $L_{11} \cdot X_{12} = A_{12}$ 
    where:
       $L_{11} \in \mathbf{R}^{m_1 \times n_1}$  is a lower triangular matrix of  $A_{11}$ 
      with unitary diagonal
     $A_{12} := X_{12}$ ;

     $A_{22} := A_{22} - A_{21} \cdot A_{12}$ ;

    xGETRF( $A_{22}$ );
  end
end.

```

Fig. 2. Recursive LU factorization function of a dense matrix A equivalent to the LAPACK's xGETRF() function with a partial pivoting code.

zero. During factorization of such matrices it pays off to take advantage of the sparsity pattern for a significant reduction in the number of floating point operations and execution time. The major issue of the sparse factorization is the aforementioned fill-in phenomenon. It turns out that the proper ordering of the matrix, represented by the matrices P and Q , may reduce the amount of fill-in. However, the search for the optimal ordering is an NP-complete problem [39]. Therefore, many heuristics have been devised to find an ordering which approximates the optimal one. These heuristics range from the divide and conquer approaches such as Nested Dissection [22,29] to the greedy schemes such as Minimum Degree [1,37]. For certain types of matrices, bandwidth and profile reducing orderings such as Re-

verse Cuthill-McKee [8,23] and the Sloan ordering [34] may perform well.

Once the amount of fill-in is minimized through the appropriate ordering, it is still desirable to use the optimized BLAS to perform the floating point operations. This poses a problem since the sparse matrix coefficients are usually stored in a form that is not suitable for BLAS. There exist two major approaches that efficiently cope with this, namely the multifrontal [20] and supernodal [5] methods. The SuperLU package [28] is an example of a supernodal code, whereas UMFPACK [11,12] is a multifrontal one.

Factorization algorithms for sparse matrices typically include the following phases, which sometimes are intertwined:

```

function xGETRF(matrix  $A \in \mathbf{R}^{n \times n}$ )
begin
  if ( $A \in \mathbf{R}^{1 \times 1}$ ) return; Do nothing for matrices of order 1.

   $n_1 := \lfloor n/2 \rfloor$ ;
   $n_2 := n - \lfloor n/2 \rfloor$ ;
  Divide the matrix A into four submatrices.
   $A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \in \mathbf{R}^{n \times n}$ 
   $A_{11} \in \mathbf{R}^{n_1 \times n_1}, A_{21} \in \mathbf{R}^{n_2 \times n_1}, A_{12} \in \mathbf{R}^{n_1 \times n_2}, A_{22} \in \mathbf{R}^{n_2 \times n_2}$ 

  xGETRF( $A_{11}$ ); Recursive call.

  Perform an upper triangular solve which is equivalent to the Level 3 BLAS xTRSM() function.
  Find  $X_{21}$  such that:  $X_{21} \cdot U_{11} = A_{21}$ 
  where:
     $U_{11} \in \mathbf{R}^{n_1 \times n_1}$  is an upper triangular matrix of  $A_{11}$ 
    (including diagonal)
   $A_{21} := X_{21}$ ;

  Perform a lower triangular solve which is equivalent to the Level 3 BLAS xTRSM() function.
  Find  $X_{12}$  such that:  $L_{11} \cdot X_{12} = A_{12}$ 
  where:
     $L_{11} \in \mathbf{R}^{n_1 \times n_1}$  is a lower triangular matrix of  $A_{11}$ 
    with unitary diagonal
   $A_{12} := X_{12}$ ;

  Compute the Schur's complement which is equivalent to a matrix-matrix multiply performed by the Level 3 BLAS xGEMM() function.
   $A_{22} := A_{22} - A_{21} \cdot A_{12}$ ;

  xGETRF( $A_{22}$ ); Recursive call.
end.

```

Fig. 3. Recursive LU factorization function used for sparse matrices (no pivoting is performed).

- matrix ordering to reduce fill-in,
- symbolic factorization,
- search for dense submatrices,
- numerical factorization.

The first phase is aimed at reducing the aforementioned amount of fill-in. Also, it may be used to improve the numerical stability of the factorization (it is then referred to as a static pivoting [18]). In our code, this phase serves both of these purposes, whereas in SuperLU and UMFPACK the pivoting is performed only during the factorization. The actual pivoting strategy being used in these packages is called a threshold pivoting: the pivot is not necessarily the largest in absolute value in the current column (which is the case in the dense codes) but instead, it is just large enough to preserve numerical stability. This makes the pivoting much more efficient, especially with the complex data structures involved in sparse factorization.

The next phase finds the fill-in and allocates the required storage space. This process can be performed solely based on the matrix sparsity pattern information without considering matrix values. Substantial performance improvements are obtained in this phase if graph-theoretic concepts such as elimination trees and elimination dags [24] are efficiently utilized.

The last two phases are usually performed jointly. They aim at executing the required floating point operations at the highest rate possible. This may be achieved in a portable fashion through the use of BLAS. SuperLU uses supernodes, i.e. sets of columns of a similar sparsity structure, to call the Level 2 BLAS. Memory bandwidth is the limiting factor of the Level 2 BLAS, so, to reuse the data in cache and consequently improve the performance, the BLAS calls are reorganized yielding the so-called Level 2.5 BLAS technique [13,28]. UMFPACK uses frontal matrices that are formed dur-

ing the factorization process. They are stored as dense matrices and may be passed to the Level 3 BLAS.

4. Sparse recursive factorization algorithm

The essential part of any sparse factorization code is the data structure used for storing matrix entries. The storage scheme for the sparse recursive code is illustrated in Fig. 5. It has the following characteristics:

- the data structure that describes the sparsity pattern is recursive,
- the storage scheme for numerical values has two levels:
 - * the lower level, which consists of dense square submatrices (blocks) which enable direct use of the Level 3 BLAS, and
 - * the upper level, which is a set of integer indices that describe the sparsity pattern of the blocks.

There are two important ramifications of this scheme. First, the number of integer indices that describe the sparsity pattern is decreased because each of these indices refers to a block of values rather than individual values. It allows for more compact data structures and during the factorization it translates into a shorter execution time because there is less sparsity pattern data to traverse and more floating operations are performed by efficient BLAS codes – as opposed to in code that relies on compiler optimization. Second, the blocking introduces additional nonzero entries that would not be present otherwise. These artificial nonzeros amount to an increase in storage requirements. Also, the execution time is longer because it is spent on floating

point operations that are performed on the additional zero values. This leads to the conclusion that the sparse recursive storage scheme performs best when almost dense blocks exist in the L and U factors of the matrix. Such a structure may be achieved with the band-reducing orderings such as Reverse Cuthill-McKee [8, 23] or Sloan [34]. These orderings tend to incur more fill-in than others such as Minimum Degree [1,37] or Nested Dissection [22,29], but this effect can be expected to be alleviated by the aforementioned compactness of the data storage scheme and utilization of the Level 3 BLAS.

The algorithm from Fig. 3 remains almost unchanged in the sparse case – the differences being that calls to BLAS are replaced by the calls to their sparse recursive counterparts and that the data structure is no longer the same. Figures 6 and 7 show the recursive BLAS routines used by the sparse recursive factorization algorithm. They traverse the sparsity pattern and upon reaching a single dense block level they call the dense BLAS which perform actual floating point operations.

5. Performance results

To test the performance of the sparse recursive factorization code it was compared to SuperLU Version 2.0 (available at <http://www.nersc.gov/~xiaoye/SuperLU/>) and UMFPACK Version 3.0 (available at <http://www.cise.ufl.edu/research/sparse/umfpack/>). The tests were performed on a Pentium III Linux workstation whose characteristics are given in Table 1.

Each of the codes were used to factor selected matrices from the Harwell-Boeing collection [19], and Tim

Davis' [10] matrix collection. These matrices were used to evaluate the performance of SuperLU [28]. The matrices are unsymmetric so they cannot be used directly with the Conjugate Gradient method and there is no general method for finding the optimal iterative method other than trying each one in turn or running all of the methods in parallel [7]. Table 2 shows the total execution time of factorization (including symbolic and numerical phases) and forward error estimates.

The performance of a sparse factorization code can be tuned for a given computer architecture and a par-

ticular matrix. For SuperLU, the most influential parameter was the fill-in reducing ordering used prior to factorization. All of the available ordering schemes that come with SuperLU were used and Table 2 gives the best time that was obtained. UMFPACK supports only one kind of ordering (a column oriented version of the Approximate Minimum Degree algorithm [1]) so it was used with the default values of its tuning parameters and threshold pivoting disabled. For the recursive approach all of the matrices were ordered using the Reverse Cuthill-McKee ordering. However, the block

end.

```

Fig. 7. Recursive formulation of the xTRSM() functions used in the sparse recursive factorization.

size selected somewhat influences the execution time. Table 2 shows the best running time out of the block sizes ranging between 40 and 120. The block size depends mostly on the size of the Level 1 cache but also on the sparsity pattern of the matrix. Nevertheless, running times for the different block sizes are comparable. SuperLU and UMFPACK also have tunable parameters that functionally resemble the block size parameter but their importance is marginal as compared to that of the matrix ordering.

The total factorization time from Table 2 favors the recursive approach for some matrices, e.g., ex11, psmigr.1 and wang3, and for others it strongly discourages its use (matrices mcfe, memplus and

Table 1

Matrix-vector multiply	100 MFLOP/s

raefsky4). There are two major reasons for the poor performance of the recursive code on the second class. First, there is an average density factor which is the ratio of the true nonzero entries of the factored matrix to all the entries in the blocks. It indicates how many artificial nonzeros were introduced by the blocking technique. Whenever this factor drops below 70%, i.e. 30% of the factored matrix entries do not come from the L and U factors, the performance of the recursive code will most likely suffer. Even when the density factor is satisfactory, still, the amount of fill-in incurred by the Reverse Cuthill-McKee ordering may substantially exceed that of other orderings. In both cases, i.e. with a low value of the density factor or excessive fill-in, the recursive approach performs too many unnecessary floating point operations and even the high execution rates of the Level 3 BLAS are not able to offset it.

The computed forward error is similar for all of the codes despite the fact that two different approaches to pivoting were employed. Only SuperLU was doing threshold pivoting while the other two codes had the threshold pivoting either disabled (UMFPACK) or there was no code for any kind of pivoting.

Table 3 shows the matrix parameters and storage requirements for the test matrices. It can be seen that SuperLU and UMFPACK use slightly less memory and consequently perform fewer floating point operations. This may be attributed to the Minimum Degree algorithm used as an ordering strategy by these codes which minimizes the fill-in and thus the space required to store the factored matrix.

6. Conclusions and future work

We have shown that the recursive approach to the sparse matrix factorization may lead to an efficient implementation. The execution time, storage requirements, and error estimates of the solution are compara-

N – order of the matrix

NZ – number of nonzero entries in the matrix

L + U – size of memory required to store the L and U factors

ble to that of supernodal and multifrontal codes. However, there are still matrices for which the recursive code does not perform well. These cases should be investigated further and possibly a metric devised that would allow selecting the best factorization method for a given matrix. This metric will probably include the aforementioned density factor. During a preprocessing phase, the density factor is computed and only if it exceeds a certain threshold the recursive code is used. An open question is which code to choose when the

recursive one is not appropriate. A performance model is necessary that links together the features of the multifrontal and supernodal approaches with the characteristics of the matrix to be factored and machine it is to be used on.

The problem with low values of the density factor may be regarded as a future research direction. The aim should be to make the recursive code more adaptive to the matrix sparsity pattern. It could allow the use of matrix orderings other than Reverse Cuthill-McKee

because the high average density of the blocks will not be as crucial any more.

Another outstanding issue is the numerical stability of the factorization process. As it is now, it does not perform pivoting and still delivers acceptable accuracy. On matrices other than those tested, the method may still fail, and even iterative refinement may be unable to regain sufficient accuracy. Therefore, an extended version that performs at least some form of pivoting would likely be much more robust.

A parallel version of the recursive approach for sparse matrices is also under consideration. At this point, there are many issues to be resolved and the main direction is still not clear. Supernodal and multifrontal approaches use symbolical data structures from the sequential algorithm to assist the parallel implementation. In the recursive approach no such structures are used and consequently parallelism has to be exploited in some other way. On the other hand, dense codes [21, 30] use recursion only locally and resort to other techniques in order to expose parallelism inherent in the factorization process [32].
