Message-Passing Performance of Various Computers *†

Jack J. Dongarra‡ Tom Dunigan §

Abstract

This report compares the performance of different computer systems for basic message-passing. Latency and bandwidth are measured on Convex, Cray, IBM, Intel, KSR, Meiko, nCUBE, NEC, SGI, and TMC multiprocessors. Communication performance is contrasted with the computational power of each system. The comparison includes both shared and distributed memory computers as well as networked workstation clusters.

1 Introduction and Motivation

1.1 The Rise of the Microprocessor

The past decade has been one of the most exciting periods in computer development that the world has ever experienced. Performance improvements, in particular, have been dramatic; and that trend promises to continue for the next several years.

In particular, microprocessor technology has changed rapidly. Microprocessors have become smaller, denser, and more powerful. Indeed, microprocessors have made such progress that, if cars had made equal progress since the day they were invented, we would now be able to buy a car for a few dollars, drive it across the country in a few minutes, and not worry about parking because the car would fit into one's pocket. The result is that microprocessor-based supercomputing is rapidly becoming the technology of preference in attacking some of the most important problems of science and engineering.

These processors are now the main stay of the workstation market.

§Oak Ridge National Laboratory

The vendors of high-performance computing have turned to RISC microprocessors for performance.

Collections of these processors are interconnected by hardware and software to attack various applications. The physical interconnection of these processors may be contained in one or more cabinets as part of a multiprocessor, or the processors may be standalone workstations dispersed across a building or campus interconnected by a local area network. The effectiveness of using a collection of processors to solve a particular application is constrained by the amount of parallelism in the application, compiler technology, message-passing software, amount of memory, and by the speed of the processors and of the interconnecting network.

1.2 Communications and Parallel Processing Systems

This report compares the results of a set of benchmarks for measuring communication time on a number of non-uniform memory access (NUMA) computers ranging from a collection of workstations using PVM [5] to machines like the IBM SP-2 and the Cray T3D using their native communication library, MPI [4], or PVM. We are interested in the communication performance for a number of reasons. First, our main interest is to obtain fundamental parameters on a given hardware platform to help in building models of execution. Second to compare machines and help in evaluating new machines and architectures as they become available.

The following section describes the critical parameters in evaluating message-passing systems. The techniques to measure these parameters are described. In section 3, the message-passing performance of several multiprocessors and networks are presented. Communication and computational performance are contrasted. Section 4 provides details for obtaining the test software.

2 Message Passing

2.1 Programming Model

Processes of a parallel application distributed over a collection of processors must communicate problem parameters and results. In distributed memory multiprocessors or workstations on a network, the information is typically communicated with explicit message-passing subroutine calls. To send data to another process, a subroutine is usually provided that requires a destination address, message, and message length. The receiving process usually provides a buffer, a maximum length, and the senders address. The programming model is often extended to include both synchronous and asynchronous communication, group communication (broadcast and multicast), and aggregate operations (e.g., global sum).

Message passing performance is usually measured in units of time or bandwidth (bytes per second). In this report, we choose time as the measure of performance for sending a small message. The time for a small, or zero length, message is usually bounded by the speed of the signal through the media (latency) and any software overhead in sending/receiving the message. Small message times are important in synchronization and determining optimal granularity of parallelism. For large messages, bandwidth is the bounded metric, usually approaching the maximum bandwidth of the media. Choosing two numbers to represent the performance of a network can be misleading, so the reader is encouraged to plot communication time as function of message length to compare and understand the behavior of message-passing systems.

Message passing time is usually a linear function of message size for two processors that are directly connected. For more complicated a networks, a per-hop delay may increase the message-passing time. Message-passing time, t_n, can be modeled as

$$t_n = \alpha + \beta n + (h-1)\gamma$$

with a start-up time, α, a per-byte cost, β, and a per-hop delay, γ, where n is the number of bytes per message and h the number of hops a message must travel. On most current message-passing multiprocessors the per-hop delay is negligible due to "worm-hole" routing techniques and the small diameter of the communication network [3]. The results reported in this report reflect nearest-neighbor communication. A linear least-squares fit can be used to calculate α and β from experimental data of message-passing times versus message length. The start-up time, α, may be slightly different than the zero-length time, and $1/\beta$ should be asymptotic bandwidth. The message length at which half the maximum bandwidth is achieved, $n_{1/2}$, is another metric of interest and is equal to $(\alpha + (h-1)\gamma)/\beta$ [10]. As with any metric that is a ratio, any notion of "goodness" or "optimality" of $n_{1/2}$ should only be considered in the context of the underlying metrics α, β, γ, and h. For a more complete discussion of these parameters see [9, 8].

There are a number of factors that can affect message-passing performance. The number of times the message has to be copied or touched (e.g., checksums) is probably most influential and obviously a function of message size. The vendor may provide hints as to how to reduce message copies, for example, posting the receive before the send. Second order effects of message size may also affect performance. Message lengths that are powers of two or cache-line size may provide better performance than shorter lengths. Buffer alignment on word, cache-line, or page may also affect performance. For small messages, context-switch times may contribute to delays. Touching all the pages of the buffers can reduce virtual memory effects. For shared media, contention may also affect performance. There also may be some first-time effects that can be identified or eliminated by performing some "warm up" tests before collecting performance data. These "warm up" tests can be simply running the test a number of times before gathering the timing data.

There are of course other parameters of a message-passing system that may affect per-

formance for given applications. The aggregate bandwidth of the network, the amount of concurrency, reliability, scalability, and congestion management may be issues.

2.2 Measurement Methodology

To measure latency and bandwidth, we use a simple echo test between two adjacent nodes. A receiving node simply echos back whatever it is sent, and the sending node measures round-trip time. Times are collected for some number of repetitions (100 to 1000) over various messages sizes (0 to 1,000,000 bytes). Times can be collected outside the repetition loop as illustrated in Figure 1. If the system has high resolution timers then a more detailed analyses can be made by timing each send-receive pair. The time for each send-receive is saved in a vector and printed at the end of the test. You can plot this vector of times, observing minimums and maximums. For small message sizes, clock resolution may not be adequate, and you will probably observe clock jitter from time-sharing interrupts in the underlying OS. The minimum send-receive time (divided by two) for zero-length messages is what we report for latency. Data rate, or bandwidth, is calculated from the number of bytes sent divided by half the round-trip time. A number of other similar tests have been reported in [6, 7].

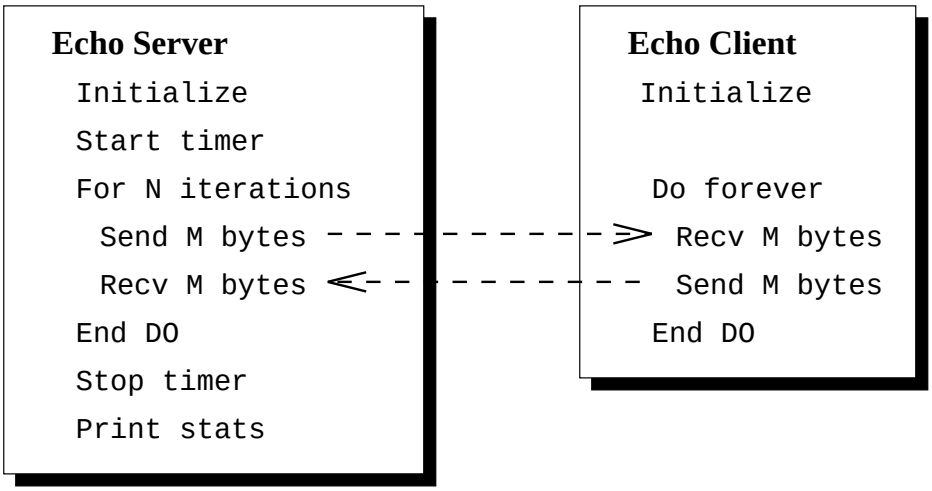

Figure 1: Echo test pseudo-code.

2.3 Latency and Bandwidth

We measured latency and bandwidth on a number of different multiprocessors. Each architecture is briefly summarized in Appendix A. Table 1 shows the measured latency, bandwidth, and $n_{1/2}$ for nearest neighbor communication. The table also includes the peak bandwidth

as stated by the vendor. For comparison, typical data rates and latencies are reported for several local area network technologies.

Table 1: Multiprocessor Latency and Bandwidth.

Machine	OS	Latency $n = 0$ (μs)	Bandwidth $n = 10^6$ (MB/s)	$n_{1/2}$ bytes	Theoretical Bandwidth (MB/s)
Convex SPP1000 (PVM)	SPP-UX 3.0.4.1	76	11	1000	250

Figure 2 details the message-passing times of various multiprocessors over a range of message sizes. For small messages, the fixed overhead and latency dominate transfer time. For large message, the transfer time rises linearly with message size. Figure 3 illustrates the asymptotic behavior of bandwidth for large message sizes. It is possible to reduce latency on the shared-memory architectures by using shared-memory copy operations. These operations usually involve only one-processor and assume that the message is ready to be retrieved on the other processor. Figure 4 compares the message transfer times for shared-memory

get's and explicit message-passing for the Cray T3D, Meiko, and NEC. Current research in "active messages" is seeking ways to reduce message-passing overhead by eliminating context switches and message copying. Finally, Figure 5 graphically summarizes the communication performance of the various multiprocessors in a two-dimensional message-passing metric space. The upper-left region is the high performance area, lower performance and LAN networks occupy the lower performance region in the lower right.

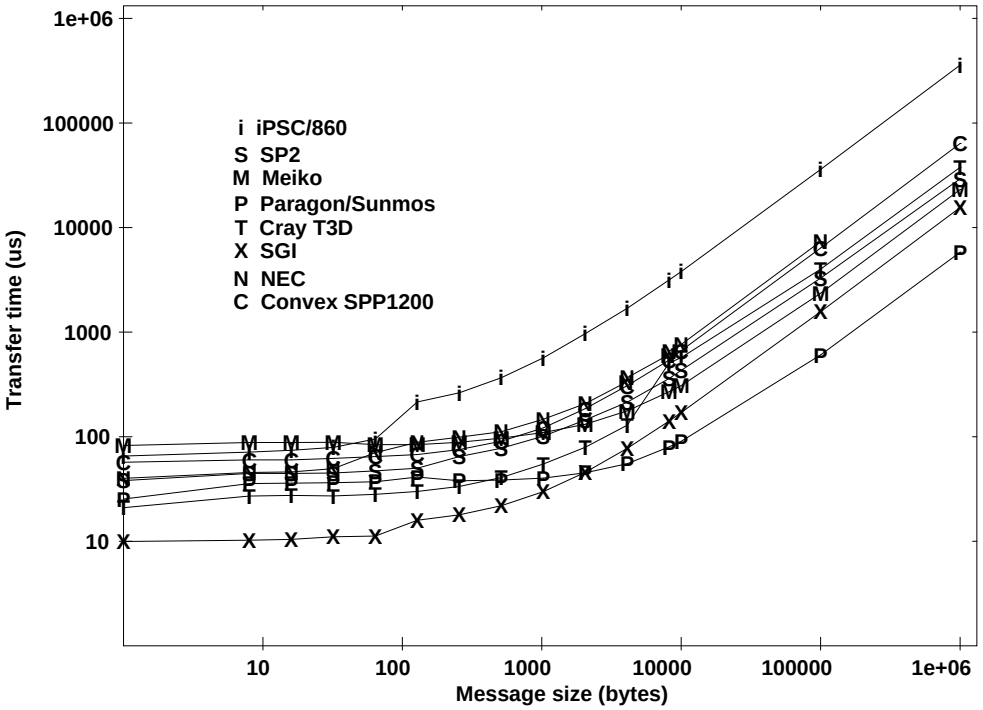

Figure 2: Message-passing transfer time in microseconds for various multiprocessors and messages sizes.

Since clusters of workstations on a network are often used as a virtual parallel machine, it is interesting to compare latency and bandwidths for various local area networks. Most communications over local area networks are done with the TCP/IP protocols, though proprietary API's may exist. We measured latency for small messages using a UDP echo test. TCP bandwidth was measured at the receiver with the *ttcp* program using 50,000 byte messages and 50,000 byte window sizes. Some newer operating systems support even larger window sizes, which could provide higher bandwidths. Most high-end workstations can transmit network data at or near media data rates (e.g., 12 MB/second for FDDI). Data rates of 73 MB/second for UDP have been reported between Crays on HiPPI (and even over a wide-area using seven OC3's) [1]. Latency and bandwidth will depend as much on the efficiency of the TCP/IP implementation as on the network interface hardware and media. As with multiprocessors, the number of times the message is touched is a critical parameter

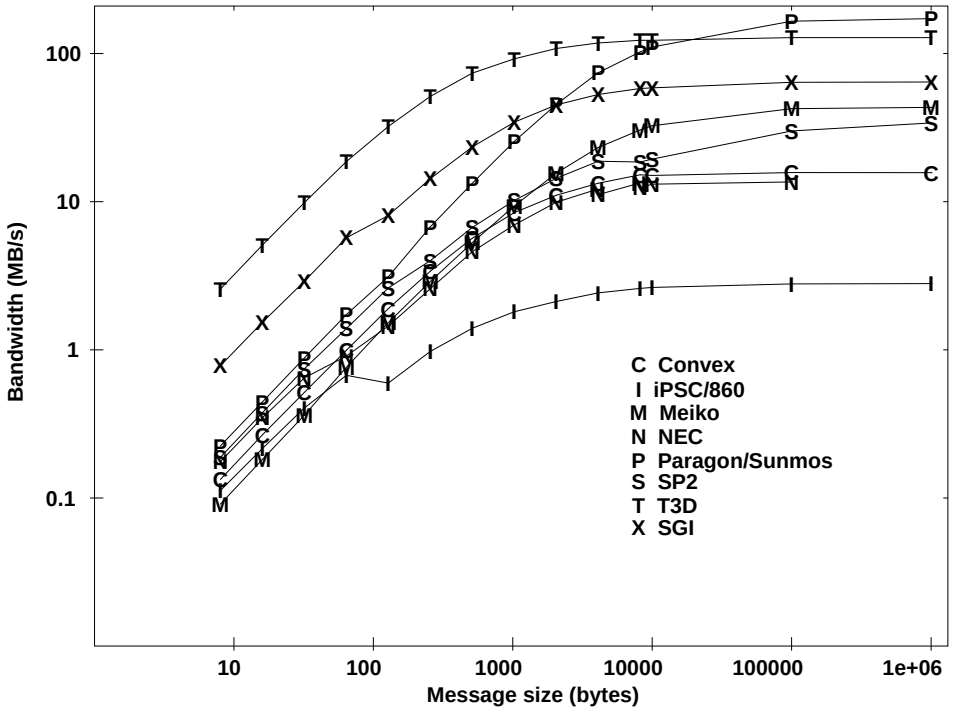

Figure 3: Bandwidth in megabytes/second for various multiprocessors and messages sizes.

as is context-switch time. Latencies for local area networks (Ethernet, FDDI, ATM, HiPPI) are typically on the order of 500 μs. For wide-area networks, latency is usually dominated by distance (speed of light) and is on the order of tens of milliseconds.

3 Computation and Communication

3.1 Performance

The performance of a computer is a complicated issue, a function of many interrelated quantities. These quantities include the application, the algorithm, the size of the problem, the high-level language, the implementation, the human level of effort used to optimize the program, the compiler's ability to optimize, the age of the compiler, the operating system, the architecture of the computer, and the hardware characteristics. The results presented for benchmark suites should not be extolled as measures of total system performance (unless enough analysis has been performed to indicate a reliable correlation of the benchmarks to the workload of interest) but, rather, as reference points for further evaluations.

Performance is often measured in terms of Megaflops, millions of floating point operations per second (Mflop/s). We usually include both additions and multiplications in the count of

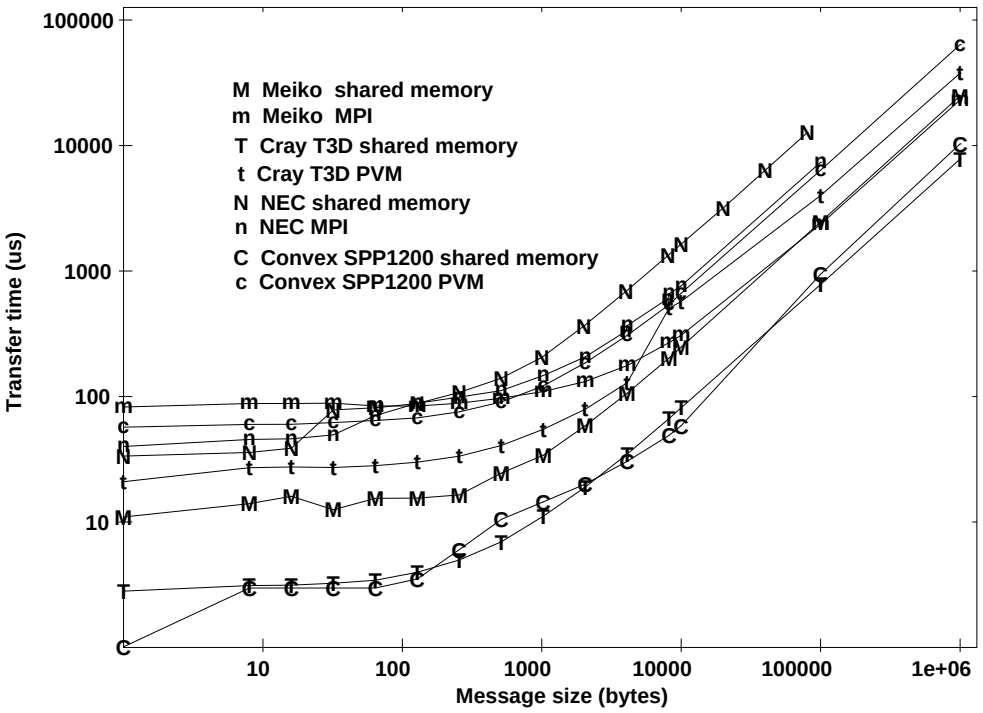

Figure 4: Transfer time in microseconds for both shared-memory operations and explicit message-passing.

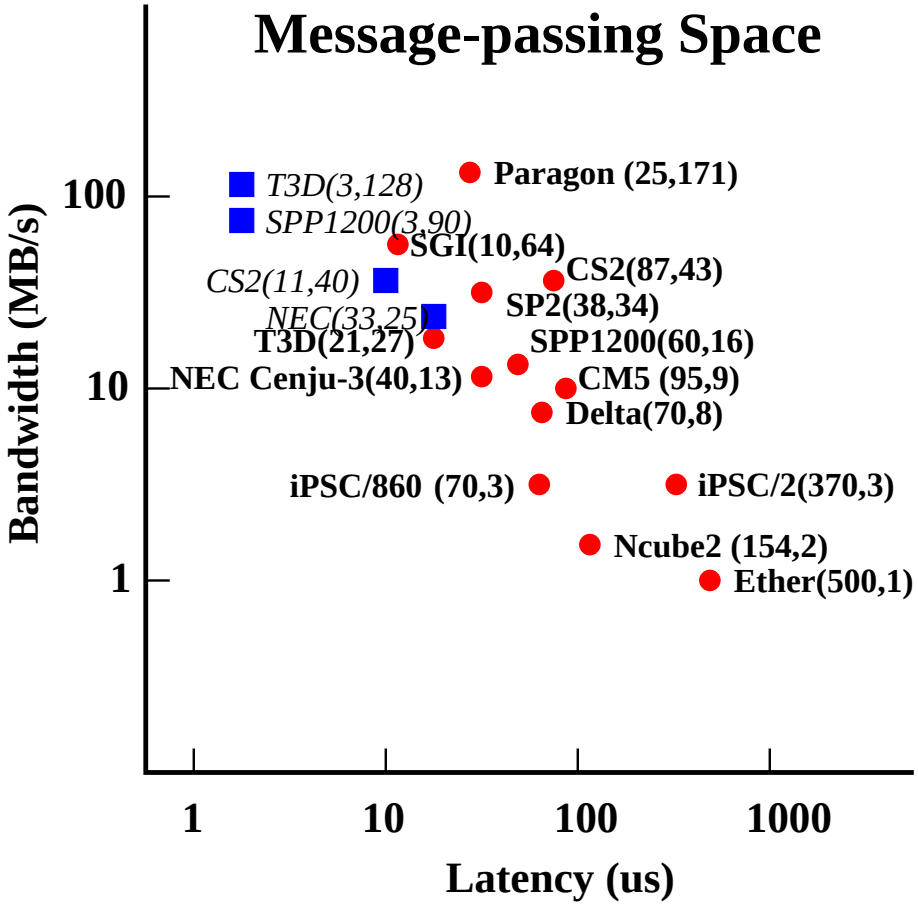

Figure 5: Latency/bandwidth space for 0-byte message (latency) and 1 MB message (bandwidth). Block points represent shared-memory copy performance.

Mflop/s, and the reference to an operation is assumed to be on 64-bit operands.

The manufacturer usually refers to peak performance when describing a system. This peak performance is arrived at by counting the number of floating-point additions and multiplications that can be performed in a period of time, usually the cycle time of the machine. As an example, the IBM SP-1 processor, has a cycle time of 62.5 MHz. During a cycle the results of the multiply/add instruction can be completed giving:

$$2\ operations/1\ cycle\ *\ 1\ cycle/16nsec\ =\ 125\ \text{Mflop/s}.$$

By peak theoretical performance we mean only that the manufacturer guarantees that programs will not exceed these rates, sort of a *speed of light* for a given computer. At one time, a programmer had to go out of his way to code a matrix routine that would not run at nearly top efficiency on any system with an optimizing compiler. Owing to the proliferation of exotic computer architectures, this situation is no longer true.

The LINPACK Benchmark [2] illustrates this point quite well. In practice, as Table 2 shows, there may be a significant difference between peak theoretical and actual performance

3.2 The LINPACK Benchmark

The LINPACK benchmark features solving a system of linear equation, $Ax = b$. The benchmark results examined here are for two distinct benchmark problems. The first problem uses Fortran software from the LINPACK software package to solve a matrix problem of order 100. That is, the matrix A has 100 rows and columns and is said to be of size 100×100. The software used in this experiment is based on two routines from the LINPACK collection: DGEFA and DGESL. DGEFA performs the decomposition with partial pivoting, and DGESL uses that decomposition to solve the given system of linear equations. Most of the time - $O(n^3)$ floating-point operations - is spent in DGEFA. Once the matrix has been decomposed, DGESL is used to find the solution; this requires $O(n^2)$ floating-point operations.

DGEFA and DGESL in turn call three BLAS routines: DAXPY, IDAMAX, and DSCAL. For the size 100 benchmark, the BLAS used are written in Fortran. By far the major portion of time - over 90% at order 100 - is spent in subroutine DAXPY. DAXPY is used to multiply a scalar, α, times a vector, x, and add the results to another vector, y. It is called approximately $n^2/2$ times by DGEFA and $2n$ times by DGESL with vectors of varying length. The statement $y_i \leftarrow y_i + \alpha x_i$, which forms an element of the DAXPY operation, is executed approximately $n^3/3 + n^2$ times, which gives rise to roughly $2/3n^3$ floating-point operations in the solution. Thus, the benchmark requires roughly 2/3 million floating-point operations.

The statement $y_i \leftarrow y_i + \alpha x_i$, besides the floating-point addition and floating-point multiplication, involves a few one-dimensional index operations and storage references. While the LINPACK routines DGEFA and DGESL involve two-dimensional arrays references, the

Table 2: Computation Performance.

BLAS refer to one-dimensional arrays. The LINPACK routines in general have been organized to access two-dimensional arrays by column. In DGEFA, the call to DAXPY passes an address into the two-dimensional array A, which is then treated as a one-dimensional reference within DAXPY. Since the indexing is down a column of the two-dimensional array, the references to the one-dimensional array are sequential with unit stride. This is a performance enhancement over, say, addressing across the column of a two-dimensional array. Since Fortran dictates that two-dimensional arrays be stored by column in memory, accesses to consecutive elements of a column lead to simple index calculations. References to consecutive elements differ by one word instead of by the leading dimension of the two-dimensional array.

If we examine the algorithm used in LINPACK and look at how the data are referenced, we see that at each step of the factorization process there are operations that modify a full submatrix of data. This update causes a block of data to be read, updated, and written back to central memory. The number of floating-point operations is $2/3n^3$, and the number of data references, both loads and stores, is $2/3n^3$. Thus, for every *add/multiply* pair we must perform a load and store of the elements, unfortunately obtaining no reuse of data. Even though the operations are fully vectorized, there is a significant bottleneck in data movement, resulting in poor performance. To achieve high-performance rates, this *operation-to-memory-reference rate* or computational intensity must be higher.

The bottleneck is in moving data and the rate of execution are limited by these quantities. We can see this by examining the rate of data transfers and the peak performance.

3.3 Restructuring Algorithms

Advanced-architecture processors are usually based on memory hierarchies. By restructuring algorithms to exploit this hierarchical organization, one can gain high performance.

A hierarchical memory structure involves a sequence of computer memories ranging from a small, but very fast memory at the bottom to a large, but slow memory at the top. Since a particular memory in the hierarchy (call it M) is not as big as the memory at the next level (M'), only part of the information in M' will be contained in M. If a reference is made to information that is in M, then it is retrieved as usual. However, if the information is not in M, then it must be retrieved from M', with a loss of time. To avoid repeated retrieval, information is transferred from M' to M in blocks, the supposition being that if a program references an item in a particular block, the next reference is likely to be in the same block. Programs having this property are said to have *locality of reference.* Typically, there is a certain startup time associated with getting the first memory reference in a block. This startup is amortized over the block move.

Processors such as the IBM RS/6000, DEC Alpha, Intel 860, etc all have an additional level of memory between the main memory and the registers of the processor. This memory, referred to as *cache.* To come close to gaining peak performance, one must optimize the use

of this level of memory (i.e., retain information as long as possible before the next access to main memory), obtaining as much reuse as possible.

In the second benchmark, the problem size is larger (matrix of order 1000), and modifying or replacing the algorithm and software is permitted to achieve as high an execution rate as possible. The algorithm used for the $n = 1000$ problem makes better use of the memory hierarchy by utilizing the data in cache. Thus, the hardware had more opportunity for reaching near-asymptotic rates. An important constraint, however, is that all optimized programs maintain the same relative accuracy as standard techniques, such as Gaussian elimination used in LINPACK.

We have converted the floating point execution rates observed for each problem to operations per cycle and also calculated the number of cycles consumed, as overhead (latency), during communication.

For the LINPACK 100 test, many processors achieve one floating point operation every four cycles, even though the processor has the ability to deliver much more than this. The primary reason for this lack of performance relates to the poor compiler generated code and the algorithm's ineffective use of the memory hierarchy. There are a few exceptions, most notably the IBM SP-2's processor. The RS/6000-590 processor is able to achieve two floating point operations per cycle for the LINPACK 100 test. The compiler and the cache structure work together on the RS/6000-590 and is able to achieve this rate.

There are also examples of poor performance on some of the first generation parallel machines, such as the nCUBE 1 and 2 and the Intel iPSC/2. These processors are able to achieve only .01 to .04 floating point operations per cycle.

For the larger test case, LINPACK 1000, most of the processors achieve 70 to 80 % of their peak.

4 Summary

This report compares a number of parallel computers for latency and bandwidth figures. From the data collected it can be seen that over time systems are capable of higher bandwidths and lower latencies. However message-passing latency is still a major concern when looked at in terms of the number of floating point operations that could be performed in the time it takes to start a message.

Appendix: Rules for Running the Tests

The software intentionally has been kept simple so that it will be easy for an experienced programmer to adapt the program, or parts of it, to a specific architecture with only a modest effort. In running the tests, the user is allowed to change the message-passing calls to the appropriate call on the specific system the program is to be run on. We have provided both PVM and MPI [4] implementations in netlib.

Appendix: Obtaining the Software

The software used to generate the data for this report can be obtained by sending electronic mail to *netlib@www.netlib.org* .

To receive the single-precision software for this benchmark, in the mail message to *netlib@www.netlib.org* type *send comm.shar from benchmark* .

To receive the double-precision software for this benchmark, type *send comm.shar from benchmark* .

A web browser can be used as well. With the url `http://www.netlib.org/benchmark/index.html` click on "benchmark/comm.shar".

Appendix: Machine Configurations for Echo Tests

A summary of the various architectures and configurations used when these performance figures were measured follows. Unless otherwise noted, the test programs were compiled with *cc -O*.

The **Convex SPP1000** and SPP1200 consist of SCI-ring connected nodes (160 MB/second). Each SPP1000 node consists of eight 100 MHz HP PA RISC 7100 processors (120 MHz for the SPP1200) with a cross-bar memory interconnect (250 MB/second). The tests were run under SPP-UX 3.0.4.1 and ConvexPVM 3.3.7.1.

The **Cray T3D** is 3-D-torus multiprocessor using the 150 MHz DEC Alpha processor. Communication channels have a peak rate of 300 MB/second. Tests were performed using MAX 1.2.0.2. A special thanks to Majed Sidani of Cray for running our communication tests on the T3D using PVM. The PVM communication was with pvm_psend and pvm_precv.

The **Intel iPSC/860** is Intel's third generation hypercube. Each node has a 40 MHz i860 with 8 KB cache and at least 8 MB of memory. Communication channels have a peak rate of 2.8 MB/second. Tests were performed using NX 3.3.2. The **Intel iPSC/2** uses the same communication hardware as the iPSC/860 but uses 16 MHz 80386/7 for computation.

The **Intel Delta** is a 512-node mesh designed as a prototype for the Intel Paragon family. Each node has a 40 MHz i860 with 8 KB cache and 16 MB of memory. Communication channels have a peak rate of 22 MB/second. Tests were performed using NX 3.3.10.

The **Intel Paragon** is a mesh-based multiprocessor. Each node has at least two 50 MHz i860XP processors with 16 KB cache and at least 16 MB of memory. One processor is usually dedicated to communications. Communication channels have a peak rate of 175 MB/second. Test were run under OSF 1.0.4 Server 1.3/WW48-02 and SUNMOS 1.6.2 (using NX message-passing).

The **IBM SP1** is an omega-switch-based multiprocessor using 62.5 MHz RS6000 processors. Communication channels have a peak rate of 40 MB/second. Tests were run using MPL.

The **IBM SP2** is an omega-switch-based multiprocessor using 66 MHz RS6000 processors with L2 cache. Communication channels have a peak rate of 40 MB/second. Tests were run using MPI. The MPI communication was with mpi_send and mpi_recv.

The **Kendall Square** architecture is a shared-memory system based on a hierarchy of rings using a custom 20 MHz processor. Shared-memory latency is about 7 μs, and bandwidth is about 32 MB/second. The message-passing performance was measured using Pacific Northwest Laboratory's *tcgmsg* library on one ring of a KSR1 running OSF R1.2.2.

The **Meiko CS2** uses SPARC processors with 200 Mflop/s vector co-processors. The communication topology is a fat tree with peak bandwidth of 50 MB/second. The MPSC message-passing library was used for the echo tests. Meiko notes that using point-to-point bidirectional channels in the echo test reduces latency from 82 microseconds to 14 microseconds. A special thanks to Jim Cownie of Meiko for running our communication tests.

The **Ncube** hypercube processors are custom processors with hypercube communication integrated into the chip. The first generation chip ran at 8 MHz, the second generation chip ran at 20 MHz.

The **NEC Cenju-3** results are from a 75 MHz VR4400SC MIPS processor with 32 KBytes of primary cache and 1 MByte of secondary cache using MPI under the Cenju Environment Release 1.5d. Communication channels have a peak rate of 40 MB/second through a multistage interconnection network.

The **SGI** results are from a 90 MHz PowerChallenge using MPI under IRIX 6.1. The SGI is a shared-memory multiprocessor using a 1.2 GB/s bus.

The **TMC CM5** is hypertree multiprocessor using 32 MHz SPARC processors with four vector units and 16 MB of memory per node. Communication channels have a peak rate of 20 MB/second. Tests were run using the message-passing library CMMD 2.0.
